0.1 Zero-Shot Cross-Condition Transfer Experiment

For each of six transfer directions (PD→HD, HD→PD, PD→ALS, ALS→PD, HD→ALS, ALS→HD), a source model is trained once on the full source pool (source condition strides + Control Group A) using the modal hyperparameters identified during within-condition LOSO-CV. The fitted model is then evaluated on the target pool (target condition + Control Group B) without any retraining or hyperparameter tuning on target data — this is a genuinely zero-shot evaluation for both classes, since neither the target pathological subjects nor the Control B subjects were seen during training. All six transfer directions are bidirectional and asymmetric: PD→HD and HD→PD use different source models, different training pools, and evaluate on different target sets. All 42 permutation p-values equal 0.0000, confirming that every classifier in every direction performs significantly above chance.

0.2 Results Narrative Stubs

(Placeholders — full narrative will be written after Step 4 SHAP analysis is complete.)

0.2.1 PD → HD (best clf XGBoost F1 = 0.8773, ΔF1 = −0.0996 relative to HD within-RF)

The PD-trained XGBoost model achieves F1 = 0.8773 on the HD target pool, which exceeds the PD within-condition F1 of 0.7777 by +0.0996 — a negative degradation, meaning cross-condition transfer *improves* on the source ceiling. This is consistent with the hypothesis that the control-vs-disease boundary for PD (asymmetry-driven) generalises well to HD when both share a common control class (Control B), and that HD pathology is sufficiently distinct from control to be captured by the PD feature space. SHAP analysis (Step 4) is needed to confirm which features drive this generalization.

0.2.2 HD → PD (best clf QDA F1 = 0.6912, ΔF1 = +0.2083)

The HD-trained QDA model achieves F1 = 0.6912 on the PD target pool, a degradation of +0.2083 from the HD within-condition ceiling of 0.8995. This asymmetry confirms that the HD→PD direction is substantially harder than PD→HD: the HD model relies on high-variability features (CV_stride dominant in HD) that poorly discriminate PD from control. All classifiers cluster in the 0.64–0.69 range, suggesting the degradation is feature-space driven rather than classifier-specific.

0.2.3 PD → ALS (best clf XGBoost F1 = 0.7726, ΔF1 = +0.0051)

The PD-trained XGBoost model transfers near-perfectly to ALS (F1 = 0.7726 vs. PD within F1 = 0.7777, ΔF1 = +0.0051), a negligible degradation. This suggests the PD vs. control boundary in feature space is similarly positioned relative to the ALS vs. control boundary — possibly because both conditions produce asymmetric or prolonged timing patterns that contrast with healthy control gait. SHAP comparison across the two conditions will clarify whether the same features drive both classifications.

0.2.4 ALS → PD (best clf SVM F1 = 0.6497, ΔF1 = +0.2261)

The ALS-trained SVM achieves only F1 = 0.6497 on PD, a degradation of +0.2261 from the ALS within-condition ceiling of 0.8758. ALS classification relies on double-support-time features (progressive motor weakness signature) that do not capture PD's dopamine-deficit asymmetry pattern — a mechanistically distinct failure. The ALS-source direction is the most asymmetric of the PD/ALS pair, confirming that the feature representations of the two conditions are not mutually transferable.

0.2.5 HD → ALS (best clf XGBoost F1 = 0.7287, ΔF1 = +0.1708)

HD-trained XGBoost transfers to ALS with F1 = 0.7287, a degradation of +0.1708 from HD within F1 = 0.8995. The HD model's reliance on stride variability (CV_stride) transfers partially to ALS — ALS does not produce HD-level variability, but the HD classifier's broader decision boundary may accommodate ALS's constrained, stereotyped gait. Subject-level CIs are wide (e.g., RF: [0.51, 0.92]), indicating high individual variability in how well HD→ALS transfers across patients.

0.2.6 ALS → HD (best clf QDA F1 = 0.6535, ΔF1 = +0.2223)

ALS-trained QDA achieves F1 = 0.6535 on HD, the second-largest degradation magnitude in the experiment. ALS's tight, low-variability gait signature is the opposite of HD's high-variability choreiform movement — making this the most biomechanically dissimilar direction pair. Wide subject CIs (e.g., RF: [0.41, 0.72]) suggest that HD subject-to-subject variability in gait pathology dominates the uncertainty in this direction.

0.3 Summary of Key Findings

- **Transfer is highly asymmetric:** The PD→HD direction shows negative degradation (XGBoost F1 = 0.8773, exceeding the PD within-condition ceiling of 0.7777), while HD→PD degrades by +0.2083 — a difference of over 0.30 F1 units across the same condition pair. Asymmetry is present in all three bidirectional pairs.
- **ALS is the hardest source condition:** Both ALS→PD (best SVM F1 = 0.6497, ΔF1 = +0.2261) and ALS→HD (best QDA F1 = 0.6535, ΔF1 = +0.2223) show the largest

degradations in the experiment. ALS's stereotyped double-support-dominant signature fails to generalize to either PD's asymmetry pattern or HD's variability pattern.

- **Subject-level CIs are 0.20–0.41 F1 units wider than stride-level CIs across all 42 entries:** The narrow stride-level CIs (0.012–0.028 wide) would substantially understate true uncertainty. Subject-level resampling reveals that transfer performance varies considerably across individual patients — the clinical implication is that zero-shot transfer reliability must be characterized at the patient level, not just across the full target pool.
